Abstract

Background: *Vibrios* are aquatic bacteria causing vibriosis in humans and aquatic animals. Vibriosis is a significant disease of cultured and wild fish.

Aim: The present study aimed to address the impact of *Vibrios* on the health status of *Trachurus trachurus* inhabiting the coastal area of Tripoli.

Methods: A total of 100 samples of (*T. trachurus*) were collected randomly from the Western Coast of Tripoli and Bab Al-Baher market, throughout the period from spring 2019 to summer 2019. All the sampled fish were examined externally and internally and lesions were recorded. Bacterial isolation from the liver and kidney was carried out using the appropriate culture media. Tissue samples were taken from the liver, kidney, and spleen in 10% neutral buffered formalin for a histopathology examination. The tissue sections were stained with hematoxylin and eosin to assess morphologically and Perl's Prussian blue for the demonstration of ferric iron.

Results: On average 69% of the infected fish exhibited at least one pathological lesion. *Vibrios* were recovered from 90% of the examined fish. The histopathological changes of the liver showed severe congestion of blood vessels (BVs), mononuclear cell infiltration surrounding a bile duct, granular degeneration and coagulative necrosis of hepatocytes in the centrilobular area, marked vacuolar degeneration of hepatocytes, activation of melano-macrophage centers (MMCs), multiple cysts of nematode in hepatic tissue (incidental finding). The histopathological alterations of the kidney showed severe congestion of BVs, vacuolar degeneration of the renal tubular epithelium, severe interstitial mononuclear cell infiltration, and marked activation of MMCs in the kidney. Moreover, congestion of BVs and marked activation of melano-macrophages (MMCs) were found in the spleen. The MMCs of most of the sampled tissues showed a strong positive reaction for ferric iron.

Conclusion: The polluted aquatic environment by sewage at Tripoli Coast is an essential factor for triggering the pathogenicity and invasion of *Vibrios* to vulnerable Atlantic horse mackerel. Also, this study is a preliminary step to give a baseline for further future studies on epidemiology and control of *Vibrio* infection in Libyan fish.

Keywords: Atlantic horse mackerel, *Vibrionaceae*, Histopathological changes, Melano-macrophages centers.

Introduction

Globally, there is an increase in diseases associated with *Vibrios* that has a great impact on marine animals and humans (Roux *et al.*, 2015). *Vibrios* are aquatic bacteria and ubiquitous in the marine environment causing vibriosis in aquatic animals and humans (de Souza Valente and Wan, 2021). It is considered a serious problem with severe economic losses worldwide. Symptoms of vibriosis in fish include anemia, ascites

fluid, intestinal necrosis, petechial hemorrhages in the muscle wall, and liquid in the air bladder (El-Sharaby *et al.*, 2018).

Vibriosis is considered a very important zoonotic disease. *Vibrio* infection in humans is associated with clinical symptoms like gastroenteritis or primary septicemia due to the consumption of raw or undercooked contaminated seafood. It can cause death in aquatic animals and humans (Helmi *et al.*, 2020; de Souza Valente and Wan, 2021). Every year, vibriosis

*Corresponding Author: Yousef M. Abouzeed. Department of Microbiology and Parasitology, Faculty of Veterinary Medicine, University of Tripoli, Tripoli, Libya. Email: y.abouzeed@uot.edu.ly

causes 80,000 diseases and 100 deaths in the United States (Newton *et al.*, 2012).

Seafood has become a very important source of protein in the humans diet in recent years because it contains all essential amino acids and is easier to digest than animal protein (Balami *et al.*, 2019). The Carangidae family has about 25 genera and 200 species (El Achi *et al.*, 2021). Atlantic horse mackerel fish belongs to the large carangidae “perciforms” family (Carbonara *et al.*, 2012). The genus *Trachurus* has three species: *Trachurus trachurus*, *Trachurus mediterraneus* and *Trachurus picturatus*. Most of the species are predators “pelagic feeders” that predate on planktonic organisms (Erdogan *et al.*, 2016).

Atlantic horse mackerel is a popular commercial fish in public markets. It is very popular for consumers in Turkey, Spain, and North African countries, having an annual catching value of 12,213.2 tons (Ab Rahman *et al.*, 2015; Tosun *et al.*, 2016; Balami *et al.*, 2019). Moreover, it is considered a migratory fish species that is indigenous to the Mediterranean, and Black Sea (Abaunza *et al.*, 2008; Aksissou and Casal, 2013).

Recently, the interaction between animal health, human health, and environmental health have been recognized as one health (OH) concept (Bukha *et al.*, 2022). OH concept is the incorporation of the direct impact of the environment on animal and human health (Bonilla-Aldana *et al.*, 2020; Jorwal *et al.*, 2020). Therefore, the quality of the marine ecosystem is essential for maintaining human health (Rahman *et al.*, 2020). The Mediterranean and Black Sea fisheries are threatened by the effects of increased pollution from human activities. Several Mediterranean countries are dumping their sewage into the seashores without treatment (FAO, 2016). However, Sewage can be loaded with pathogenic microorganisms that can seriously contaminate coastal waters. This microorganism can be taken up by fish, shellfish, and other aquatic organisms, thus increasing the possibility of their entry into the food chain of fish (Zutshi and Prasad, 2008; FAO, 2016).

Globally, *Vibrio* infection is a threat to public health, which is related to fisheries. Difficulty in minimizing the spread of vibriosis due to the widespread of the *Vibriosis* and its high ability to persist in the aquatic environment (Osunla and Okoh, 2017). In Libya, there is no previous data about the detection of *Vibriosis* affecting Atlantic horse mackerel. Thus, the current study was designed to address the impact of *Vibriosis* on the health status of highly commercial Atlantic horse mackerel (*T. trachurus*) inhabiting the Western Coast of Tripoli, Libya and describe the possible pathological lesions that might be associated with *Vibrio* infection. Finally, to underline the risk that may pose to public health.

Material and Methods

Fish sampling

A total of 100 samples of Atlantic horse mackerel (*T. trachurus*) were collected randomly from the Western Coast of Tripoli and Bab Al-Baher market, throughout

the period from spring 2019 to summer 2019. A total of 50 samples were collected seasonally, 40 fresh fish were collected directly from the fisherman on the boat after catching, and 10 fish were collected from Bab-Albahr market. Fish samples were kept on crushed ice in an insulated icebox and transferred to the Laboratory of Poultry and Fish Diseases, Faculty of Veterinary Medicine, University of Tripoli, Tripoli, Libya.

Sample processing

Fish were flushed with ethanol 70% to get rid of external contaminants. Using the three-line technique (Triangular incision) fish were cut open from the left side to expose internal organs. Fish were externally and internally examined for any possible lesions which were photographed using a digital camera (Sony, Japan).

Bacterial isolation

The modified protocol by Austin *et al.* (2012) was used for bacterial isolation. After clinical examination of the samples, liver, and kidney materials were inoculated onto alkaline peptone water (APW) tubes supplemented with 2% NaCl and incubated at 25°C–27°C for 24 hours. Aliquots from inoculated APW tubes were streaked onto modified Thiocitrate Bile Salt Sucrose Agar (TCBS) and onto MacConkey agar (Oxoid, UK). Each media was supplemented with 1%–2% NaCl. The inoculated plates were then incubated at 25°C–27°C for 24–72 hours at maximum. The plates were inspected for any possible colonial growth. The culture characteristics of the retrieved colonies were recorded. Morpho-chemical characterizations were performed using conventional biochemical tests (Gram stain, oxidase, and catalase).

Histopathological examination

Tissue specimens were taken from the affected organs (liver, kidney, and spleen) and were fixed in 10% buffered formalin for later processing and examination, according to Bancroft and Gamble (2008). The stained tissue sections hematoxylin and eosin (H&E) and Perl's Prussian blue stain were examined under the light microscope (ZEISS, Germany).

Results

Clinical findings

Most of the macroscopical examined fish exhibited typical signs of septicemic diseases including hemorrhagic patches on different areas on the surface of fish and the base of the fins, ascites, and congestion of internal organs. On average 69% of the infected fish exhibited at least one lesion. The external lesions during the spring and summer seasons were hemorrhages at the base of the pectoral fin and around the operculum, congestion of pelvic, caudal, and anal fins (Fig. 1a and b). While internal lesions were splenomegaly, pale liver, congested liver, hemorrhagic liver, kidney, and swim bladder (Fig. 1c–e).

Percentages of sampled fish with external lesions from the spring to the summer

During the spring season, a high percentage of the fish showed hemorrhage at the base pectoral fin 22%, and

Fig. 1. Atlantic horse mackerel naturally infected with *Vibrio* species showing: (a) congestion of caudal fin (white arrow) and anal fin (black arrow). (b) Hemorrhage at the base of pectoral fin (black arrow) and around the operculum (white arrow) in addition to congestion of pelvic fin (asterisk). (c) Congested liver (white arrow), mild hemorrhage in swim bladder (black arrow), severe hemorrhage in kidney (white arrow), and splenomegaly. (d) Pale liver (white arrow). (e) Severe hemorrhagic liver (white arrow) and kidney (black arrow).

just 3% exhibited congested caudal fin 3% (Fig. 2). However, during the summer season, a high percentage of the fish showed hemorrhage around the operculum 38%, and only 2% showed dark pigmentation patches on the skin (Fig. 3).

Percentages of sampled fish with internal lesions from the spring to the summer

During the spring season, a high percentage of the fish showed pale liver 20%, but only 6% of the fish showed hemorrhage on all internal organs (Fig. 4). Whereas, during the summer season 20% of the fish showed pale liver and 2% splenomegaly (Fig. 5).

Bacteriological examination

Morphological, culture characters, and biochemical identification

On modified TCBS medium the retrieved colonies appeared as circular yellow or green colonies ranging from pinpoint to 2–3 mm characteristic of *Vibrio* spp. (Fig. 6a and b). On the MacConkey medium the retrieved colonies were circular colorless colonies ranging from pinpoint to 2 mm (Non-lactose fermenting), and circular dark pink colonies (Lactose fermenting) (Fig. 7a and b). Bacteria were Gram-negative curved rods, oxidase, and catalase-positive.

Prevalence of *Vibrio* retrieved *Vibrio* isolates from sampled fish

The data revealed that *Vibriosis* was recovered from 90% (90/100) of the examined fish during two samplings

(spring and summer) (Fig. 8). While the prevalence of *Vibrio* isolates that were isolated from examined fish obtained from the Bab Albahr fish market was 100% during summer and 60% during the spring season (Fig. 9).

Histopathological examination

Histopathological examination of kidney tissue of Atlantic horse mackerel naturally infected with *Vibrio* species showed severe congestion of blood vessels (BVs), vacuolar degeneration of the renal tubular epithelium, severe interstitial mononuclear cell infiltration, and marked activation of melanomacrophages centers (MMCs) (Fig. 10a and b). While examination of the spleen revealed severe congestion of BVs and marked activation of MMCs (Fig. 10c). Histopathological examination of liver tissue exhibited severe congestion of BVs, mononuclear cell infiltration of portal triads and hyperplasia of the bile duct (Fig. 11a and b). The hepatocytes showed degenerative changes in the form of granular and vacuolar degeneration in addition to coagulative necrosis (Fig. 11c and d). Mild activation of MMCs was also seen (Fig. 11e). In some hepatic tissue, multiple cysts of nematode were observed (incidental finding) (Fig. 11f). The MMCs of most of the sampled tissues showed a strong positive reaction for ferric iron (Fig. 12).

Discussion

Fish health problems mainly are related to aquatic environmental stress. However, any disease conditions

are the outcome of the interaction between three dynamic factors: pathogen, susceptible host, and environmental stress (Austin 2011; Austin *et al.*, 2012; Rehman *et al.*, 2015; Eissa *et al.*, 2017). Many

Mediterranean countries are directly dumping their municipal sewage into seashore without any treatments (Eissa *et al.*, 2015). Moreover, untreated wastewater can possibly transfer zoonotic pathogens from land to

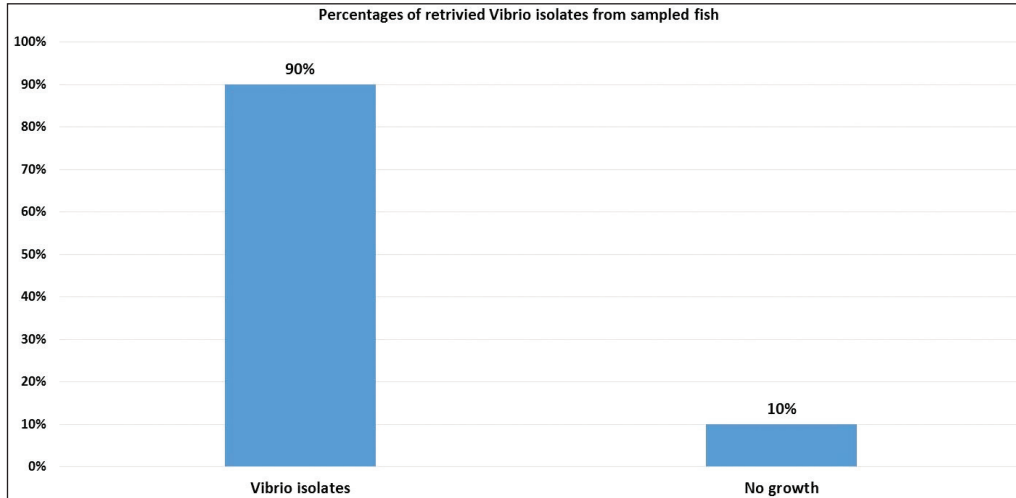

Fig. 8. Percentages of total retriived *Vibrio* isolates from sampled fish.

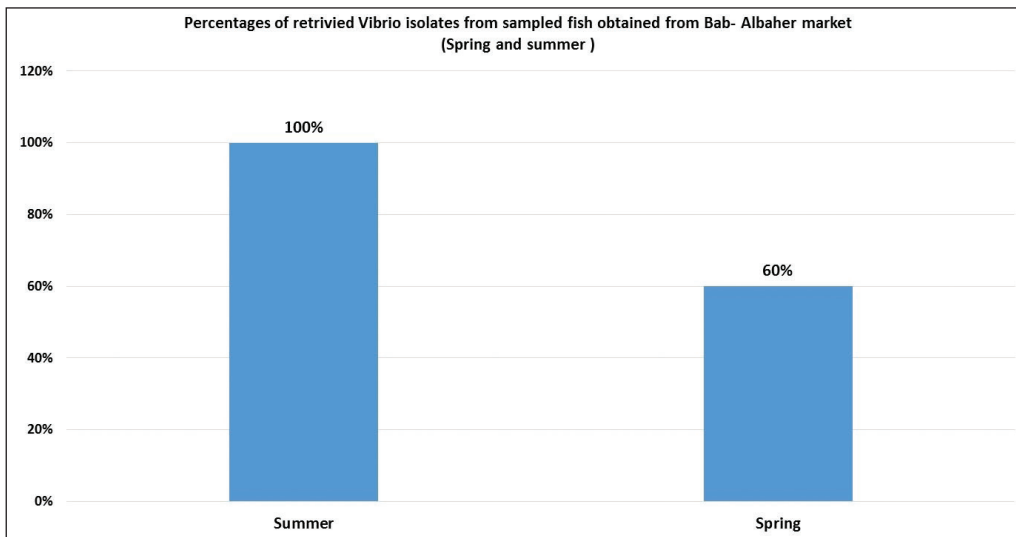

Fig. 9. Percentages of retriived *Vibrio* isolates from sampled fish obtained from Bab-Albahr market collected during spring and summer of 2019.

the sea, leading to increasing the possibility of entering pathogenic organisms into the food chain of fish (Eissa *et al.*, 2015, 2017). Several bacterial infections of public health concerns such as Vibriosis, Mycobacteriosis, and streptococcosis have been reported in many fishes of the Mediterranean Basin. These pathogenic bacteria are usually associated with food-borne illnesses through consumption of insufficiently cooked fish (Eissa *et al.*, 2015). *Vibriosis* are critically serious pathogens that can cause fatal diseases in aquatic animals and humans.

In this study, high percentages of Atlantic horse mackerel with several external pathological lesions have been found during the spring and summer of 2019. Whereas, the numbers of fish samples without pathological lesions were quite low.

Interestingly, our data revealed that around 69% of the examined Atlantic horse mackerel collected from the

Western Coast of Tripoli, Libya have shown typical signs (lesions) of severe *Vibrio* infection which is coincided with bacteriological results. Our results are consistently in accord with results obtained by Mohamad *et al.* (2019) have reported 60% of the examined fish that showed pale and hemorrhagic livers, hemorrhagic kidneys, ulcerative lesions, and focal hemorrhages. Furthermore, the examined fish that showed one or more pathological lesions also had a positive culture for *Vibrio* species. Also, this is in accordance with previous findings observed by Boran *et al.* (2013) who have found hemorrhage on the liver, enlarged spleen and dark pigmentation, ascities, and petechial hemorrhage on the abdomen of examined horse mackerel.

Some of the examined horse mackerel in the current study were considered apparently normal nonetheless their

Fig. 10. Histopathological findings in the kidney and spleen of Atlantic horse mackerel naturally infected with *Vibrio* species. (a and b) Kidney showing severe congestion of BVs (asterisk), vacuolar degeneration of the renal tubular epithelium (white arrows), severe interstitial mononuclear cell infiltration (black arrows) and marked activation of MMCs. (c) Spleen showing congestion of BVs (black arrows) and marked activation of MMCs (H&E stain: a and c $\times 20$; b $\times 40$).

culture results were positive for *Vibrio* spp. Moreover, Eissa *et al.* (2017) reported higher percentages of the examined common panadora (*Pagellus erythrinus*) from the coast of Tripoli were apparently normal yet they were positive for *Vibrio* spp., these findings are totally concurred with the results of the current study. The present study has revealed that the prevalence of *Vibrio* in examined Atlantic horse mackerel was 90% (90/100) during the study period, spring and summer season of 2019. However, nearly similar results were reported by Tan *et al.* (2017) who have found a high prevalence of 89.2% (116/130) of *Vibrio* in mackerel fish. The study of El-Sharaby *et al.* (2018) revealed that *Vibrio* spp. was successfully recovered from 39% of examined fish collected from the Delta region, Egypt, this is agree with the results of the current study. The discrepancy in results between previous studies and the study herein can be attributed to many factors including the sample size, species of the fish, water quality, season, and area of collection. Our study is in accordance with other studies investigated *Vibrio* spp. infection in different fish species from the Libyan Coasts (Madi *et al.*, 2006; Elsharif *et al.*, 2007; Madi

et al., 2015a, 2015b). To the best of our knowledge, this is the first report on isolation of *Vibrio* spp. from *T. trachurus* from Tripoli Coast.

Our results revealed that the prevalence of *Vibrio* isolates from examined Atlantic horse mackerel obtained from the Bab Albahr market was 100% during summer. Our results fall within the range reported by Tan *et al.* (2017) where the prevalence of *Vibrio* in horse mackerels from wet markets was (97%) followed by minimarkets (89.1%) and hypermarkets (83.3%). Our findings are also in agreement with the study of Bakr *et al.* (2011) who determined the presence of *Vibrios* in 52% of samples obtained from different markets in Alexandria.

Vibrio infected Atlantic horse mackerel examined herein concurrently showed notable histopathological changes with marked activation of MMCs. Furthermore, the presence of hemosiderin in MMC has been demonstrated by Perl's Prussian blue stain and confirmed that phagocytic melanocytes accurately dependent on iron content, which is produced during the deterioration of red blood cells in response to

Fig. 11. Histopathological findings in the liver of Atlantic horse mackerel naturally infected with *Vibrio* species. Photomicrographs showing (a) severe congestion of BV; (b) mononuclear cell infiltration surrounding a bile duct (white arrows); (c) granular degeneration (white arrows) and coagulative necrosis (black arrows) of hepatocytes in centrilobular area; (d) marked vacuolar degeneration of hepatocytes (black arrows); (e) activation of MMCs; and (f) multiple cysts of nematode in the hepatic tissue (black arrows) (incidental finding) (H&E stain; a, e, and f $\times 10$; c $\times 20$; b and d $\times 40$).

Fig. 12. Histological section of liver of Atlantic horse mackerel showing positive staining reaction for hemosiderin (black arrows) (Perl's Prussian blue stain, $\times 20$).

immune system activation and possibly lead to MMC formation (Handy and Penrice, 1993).

The results of histopathological examination are in accordance with the previous study of Eissa *et al.* (2015) that revealed the presence of severe renal tubular degeneration and necrosis of renal tubular in the kidney, severe MMC activation in the splenic tissue sections, and focal necrosis of hepatic tissue, and severe vacuolar degeneration of hepatic cords in the liver sections.

The histopathological changes were less prominent in bacteriological negative culture specimens. The appearance of histopathological lesions on the organs of *T. trachurus* refers to the septicemia nature of Vibriosis infection. In addition, these lesions confirm our hypothesis that the biological pollutants in swage hold many pathogenic bacteria and parasites which can seriously contaminate coastal waters. These pathogens can be taken up by zooplanktons as shellfishes, thus increasing the possibility of their entry into the food chain of the fish. During spawning season, Atlantic horse mackerel approaches the coastal area where it feeds on these contaminated crustaceans. This can really compromise the immunity of the fish and increases the

likelihood of bacterial and parasitic infection which will eventually enter the human food chain.

In our study, nematodes larvae were observed in some histological sections of the liver (incidental findings). Interestingly, there were no host inflammatory reactions seen in these sections. Several studies have been conducted on different types of fish from the coast of Tripoli, and revealed that there is an aquatic model of Nematode/*Vibrio* concurrent infection in the examined fish, this is consistent with our findings (Eissa *et al.*, 2017, 2018).

Conclusion

The isolation of *Vibrios*, finding nematodes larvae, and high numbers of MMCs in histological sections are highly indicative of the deteriorated seawater quality and clear evidence of sewage contamination of the coastal area of Tripoli-Libya. An ongoing dynamic problem caused by the random dumping of untreated municipal sewage into the marine environment can adversely affect fish and human health. *Vibrio* infection within Libyan fishes has not been widely studied with many gaps in these studies. Therefore, these gaps need to be more studied in future research.
